**Abstract.** The rapid detection of compact binary coalescence with a network of advanced gravitational-wave detectors will offer a unique opportunity for multimessenger astronomy. Prompt detection alerts to the astronomical community may make it possible to observe the onset of electromagnetic emission from compact binary coalescence. We demonstrate a computationally practical analysis strategy that produces early warning triggers even before gravitational radiation from the final merger has arrived at the detectors. With current rate estimates for the Advanced LIGO design configuration, we should detect  $\sim 10$  sources earlier than 10 seconds before merger in 1 year of livetime.

## 1. Introduction

The coalescence of compact binary systems consisting of neutron stars (NS) and/or black holes (BH) is the most promising source of gravitational radiation for Advanced LIGO [1], Virgo [2], GEO [3], and LCGT [4]. Tens of binary coalescence events are expected to be observed in the advanced detector era later this decade [5].

As a compact binary system loses energy to gravitational waves, its orbital separation decreases. This causes a run-away inspiral with the gravitational-wave amplitude and frequency increasing until the system eventually merges near the innermost stable circular orbit (ISCO). If a neutron star is involved it may

*Would the introduction be more effective without this paragraph?*

become tidally disrupted near the merger. This disrupted matter can fuel a bright electromagnetic counterpart in the system’s final moments as a binary [6].

Prompt electromagnetic emission can arise as shells of relativistically outflowing matter collide in the inner shock. Such an inner shock from a compact binary coalescence is believed to be a mechanism for short gamma-ray bursts (short GRBs) [7, 8]. The same inner shocks, or potentially reverse shocks, can produce a bright accompanying optical flash [9]. Prompt emission is a probe into the extreme initial conditions of the outflow, in contrast with afterglows, which are relatively insensitive to initial conditions. Optical flashes have only been observed for a handful of long GRBs [10, 11, 12, 13, 14, 15] by telescopes with extremely rapid response or, in the case of GRB 080319B, by pure serendipity, where several telescopes were observing a previous GRB in the same field [14]. Short GRBs, on the other hand, typically fade too quickly to observe past the initial burst of gamma rays and hard x-rays. Rapid gravitational-wave transient alerts could enable the observation of optical flashes from short GRBs. An optical counterpart would vastly boost confidence in the gravitational-wave detection and provide the tight sky localization necessary to allow determination of the source’s host galaxy, which leads to a redshift measurement. With both redshift and a coincident gravitational-wave observation, we can produce precision measurements of the Hubble constant [16].

To this end, we have the ambition of reporting candidates not minutes *after* the merger, but seconds *before*. By looking for threshold crossings before the gravitational-wave signal leaves the detection band, it is possible to trade some signal to noise ratio (SNR) for latency. Figure 1 shows projected early trigger rates for NS–NS binaries in Advanced LIGO assuming the event rate predictions in [5].

The gravitational-wave community initiated a project to send alerts when potential gravitational-wave transients are observed. In October 2010, LIGO completed its sixth science run (S6) and Virgo completed its third science run (VSR3). While both LIGO detectors and Virgo were operating, several all-sky detection pipelines operated in a low-latency configuration, namely MBTA, ihope, Coherent WaveBurst, and Omega [20, 21]. The S6 analyses achieved latencies of 30–60 minutes, which were dominated by a human vetting process. Candidates were sent for electromagnetic followup to several telescopes; Swift, ROTSE, TAROT, and Zadko [22, 20] took images of likely sky locations. MBTA achieved the best gravitational-wave trigger generation latencies of 2–5 minutes. We assume that in the advanced detector era the vetting process will be automated, so current trigger generation and telescope actuation would then dominate latency.

Predictive detection of CBCs will require striking a balance between latency and throughput. CBC searches consist of banks of matched filters, or cross-correlations between the data stream and a bank of nominal “template” signals. There are many different implementations of matched filters, but most have high throughput at the cost of high latency, or low latency at the cost of low throughput. The former are epitomized by the overlap-save algorithm for FFT convolution, currently the preferred method in gravitational wave searches. The most obvious example of the latter is the time domain (TD) convolution, which has no latency at all. However, its computational complexity is quadratic in the length of the templates, so it is prohibitively expensive for long templates.

Fortunately, the morphology of inspiral signals can be exploited to offset some of the computational complexity of low latency algorithms. First, the signals evolve slowly in frequency, so that they can be broken into contiguous bandlimited time

*I think we should say also something about how we can also get the full SNR within moments after the coalescence, it is obvious maybe, but we should be explicit*

Figure 1: Expected number of NS–NS sources that will be detectable  $T_{\text{bc}}$  seconds before coalescence. The solid line is the most likely yearly rate estimate  $N_{\text{re}}$  for Advanced LIGO and the shaded region is the interval  $N_{\text{low}}$  to  $N_{\text{high}}$  from [5]. Note that assuming SNR 8 is sufficient for detection and that we observe  $N_{\text{re}} = 40$  events per year with a detector having the ZERO\_DET\_high\_P noise model described in [17],  $\sim 10$  sources detectable within 10 seconds of merger and  $\sim 1$  sources detectable within 100 seconds of merger. Other noise models, ZERO\_DET\_low\_P [18] and BHBH\_20deg [19] provide better results for early detection but at the cost of fewer total events observed above SNR 8.

intervals and processed at possibly lower sample rates. Second, inspiral filter banks consist of highly similar templates, admitting principal component analysis to reduce the number of templates. We described a rank-reduction scheme based on singular value decomposition in [23]. We will use both aspects to demonstrate that a very low latency analysis with predictive detection of compact binary sources is possible with current computing resources. Assuming other aspects of gravitational-wave observation latency can be reduced significantly, this should allow the possibility for prompt alerts to be sent to the astronomical community.

The paper is organized as follows. First we provide an overview of our method for detecting compact binary coalescence signals in an early-warning analysis. We then describe the pipeline we have constructed that implements our method. To validate the approach we present results of simulations and conclude with some remarks on what remains to prepare for the Advanced detector era.

## 2. Early warning searches for compact binary coalescence

In this section we describe a decomposition of the compact binary parameter space that reduces low-latency filtering cost sufficiently to allow for the possibility of early-warning detection with modest computing requirements. We expand on the ideas of [24, 25] that describe a multiband decomposition of the compact binary parameter space that resulted in search with  $\sim$ minutes latency in LIGO’s S6 and Virgo’s VSR2 science runs. We combine this with the orthogonal decomposition described in [23] that exploits the redundancy of the template banks.

### 2.1. Conventional CBC matched filter searches

Inspiral signals are parameterized by a set of intrinsic parameters  $\bar{\theta}$  that determine the amplitude and phase evolution of the gravitational wave strain. For systems where the effects of spin can be ignored, the intrinsic parameters are the component masses of the binary,  $\bar{\theta} = (m_1, m_2)$ . Searches for gravitational waves from compact binary coalescence typically employ matched filter banks that discretely sample the possible intrinsic parameters [26]. The filters for the waveforms  $h(t, \bar{\theta})$ , known as templates, are the waveforms weighted by the inverse detector noise amplitude spectral density. To construct a template bank, templates are chosen with discrete signal parameters  $\theta_1, \theta_2, \dots, \theta_N$  to assure a bounded loss of SNR [27, 28]. That is, any possible signal within the search space will have a cross-correlation of  $\geq 0.97$  with at least one template. Such a template bank is said to have a *minimum match* of 0.97. Data are filtered against each template to produce an SNR time-series. Local peak-finding across time and templates determines detection candidates. <sup>‡</sup>

We will denote the  $i^{\text{th}}$  filter with parameters  $\bar{\theta}_i$  as a function of time  $x_i(\tau)$ . In this work we will discuss transformations to a set of filters  $\{x_i(\tau)\}$ . Some of these transformations are not useful or practical over the entire parameter space. For that reason we assume from here onward that the set of filters  $\{x_i(\tau)\}$  refer to a set of near-neighbor filters that can be chosen as a subset of the full parameter space. Several such subsets can be chosen until all of the filters are a member of one local set.

Filtering the detector data  $h(t)$  involves a convolution of the data with the filter. For a unit-normalized filter, and whitened detector data, the result can be interpreted as the signal-to-noise ratio,  $\rho_i(t)$  and is defined as

$$\rho_i(t) = \int x_i(\tau) h(t - \tau) d\tau \quad (1)$$

$$= \int \tilde{x}_i(f) \tilde{h}(f) e^{-2\pi i f t} df, \quad (2)$$

where the second line is a result of the convolution theorem and  $\tilde{x}_i(f)$  is the Fourier transform of  $x_i(\tau)$  as is  $\tilde{h}(f)$  the Fourier transform of  $h(t)$ .

The evaluation of the integrals in (1) and (2) are implemented as sums over sample points for the digitized gravitational-wave detector output. Discrete Fourier transforms can be computed efficiently numerically. For that reason (2) is typically far faster, computationally. To evaluate (1) requires  $\mathcal{O}[N_{x_i} N]$  floating point operations per filter  $x_i$ , where  $N_{x_i}$  is the number of sample points in the filter  $x_i$  and  $N$  is the number of sample points in the data  $h$ . Assuming  $N_t$  filters are required, the total cost is  $\mathcal{O}[N_t N_{x_i} N]$ . However, (2) requires only  $\mathcal{O}[N \log N]$  operations per filter assuming transform lengths that are longer than the filter (i.e.  $N > N_{x_i}$ ), resulting in a total cost of  $\mathcal{O}[N_t N \log N]$ . In most cases  $N_{x_i} \gg \log N$  and the computational savings by choosing the frequency-domain integral form (2) is clear. However, to take full advantage of the computational efficiency of (2) requires an acausal knowledge of the detector data  $h(t)$ , which implies an inherent latency. In contrast, (1) can be updated every time a new sample point of detector data is taken.

<sup>‡</sup> There are two gravitational-wave polarizations,  $+$  and  $\times$ . A given detector will observe a combination of these polarizations that will largely be degenerate with an overall unknown constant phase. This can be maximized over by filtering for quadrature phases and taking the magnitude of the result. For simplicity we will ignore that aspect in this work, as it is straightforward to generalize but not necessary for understanding any of the points that will be made.

*Change this to a harpoon or vector symbol.*

*nvf: I don't think that the splitting of the bank is a crucial point here. Perhaps later if we discuss the up-front cost of the SVD.*

## 2.2. Proposed method

In order to minimize latency we propose using the time-domain convolution presented in (1). However, because the brute-force evaluation of (1) is far too costly to be useful, we will consider an approximation to (1) that can reduce substantially the cost of real-time filtering. This approximation has the form

$$\rho_i(t) \approx \sum_k^{N_{ts}} \sum_j^{N_{uj,k}} \int_{\tau_k}^{\tau_{k+1}} v_{ijk} \sigma_{jk} u_{jk}(\tau) h(t - \tau) d\tau \quad (3)$$

where  $u_{jk}(\tau)$  is an orthogonal basis set of filters spanning the space of  $\{x_i(\tau)\}$  and  $\sigma_{jk} v_{ijk}$  is a tensor relating the filters  $u_{jk}(\tau)$  to the original filter set  $\{x_i(\tau)\}$ . We claim that with a suitable choice of filters  $u_{jk}(\tau)$  one can reduce the computational cost of (1) sufficiently to feasibly search for gravitational waves from compact binary coalescence in real-time. This requires 1) exploiting the time-frequency characteristics of the binary waveforms and 2) exploiting the redundancy of the template bank. We describe our procedure for producing the decomposition in (3) in the remainder of this section.

### 2.2.1. Selectively reducing the sample rate of the data and template waveforms

The first step of the orthogonal decomposition described in (3) is to divide the templates into *time slices*. This is a time-domain analogue to the frequency-domain decomposition described in [24, 25, 29, 30]. A matched filter is constructed for each time slice. The outputs form an ensemble of partial SNR streams. By linearity, these partial SNR streams can be suitably time delayed and summed to reproduce the SNR of the full template. We will show in the next section that this, combined with the singular value decomposition, is sufficient to enable a computationally efficient time-domain search and furthermore is an essential part of an early-warning detection scheme.

For concreteness and simplicity, we will consider an inspiral waveform in the quadrupole approximation, for which the time-frequency relation is

$$f = \frac{1}{\pi \mathcal{M}} \left[ \frac{5}{256} \frac{\mathcal{M}}{-t} \right]^{3/8}. \quad (4)$$

Here,  $\mathcal{M}$  is the chirp mass of the binary in units of time (where  $GM_\odot/c^3 \approx 5\mu\text{s}$ ) and  $t$  is the time relative to the coalescence of the binary [26, 31]. Usually the template is truncated at some prescribed time  $t_0$ , or equivalently frequency  $f_{\text{max}}$ . This is often chosen to correspond to the ISCO defined previously. An inspiral signal will enter the detection band at a low frequency,  $f = f_{\text{low}}$  corresponding to a time  $t_{\text{low}}$ . The template is assumed to be zero outside the interval  $[t_{\text{low}}, t_0]$  and is said to have a duration of  $t_0 - t_{\text{low}}$ . It is critically sampled at a rate of  $2f_{\text{max}}$ .

The monotonic time-frequency relationship of (4) allows us to choose time-slice boundaries that require substantially less bandwidth at early times in the inspiral. Our goal is to reduce the filtering cost of a large fraction of the waveform by computing part of the filter integral at a lower sample rate. Specifically we consider here time slice boundaries with the next highest power-of-two sample rate that critically samples the time sliced filter. The time slices for this template consist of the  $k$  intervals  $(t_k, t_{k-1}]$ ,  $\dots$ ,  $(t_2, t_1]$ ,  $(t_1, t_0]$  sampled at frequencies  $f_{k-1}, \dots, f_1, f_0$  where  $f_0 \geq 2f_{\text{ISCO}}$ ,  $t_0 = t_{\text{ISCO}}$ ,  $f_{k-1} \geq 2f_{\text{low}}$ , and  $t_k \leq t_{\text{low}}$ . An example time-slice design satisfying these constraints for a  $1.4 - 1.4 M_\odot$  binary is shown in table 1.

Table 1: Example of nearly critically sampled, power-of-two time slices for a  $1.4 - 1.4 M_\odot$  template extending from  $f_{\text{low}} = 10$  Hz to  $f_{\text{ISCO}} = 1571$  Hz with a time frequency structure given by (4).  $f_k$  is the sample rate of the time slice,  $(t_{k+1}, t_k]$  are the boundaries in seconds preceeding coalescence and  $N_{ts,k}$  are the number of sample points in the  $k^{\text{th}}$  filter.

Rather than applying a unique time-slice decomposition to each template waveform, we find a decomposition that is adequate for the entire set  $\{x_i\}$ . This is facilitated by choosing templates in the set  $\{x_i\}$  with similar chirp masses,  $\mathcal{M}$ . The time-slice decompositions of the filters  $x_i(\tau)$  lead to new filters  $y_{ik}(\tau)$  satisfying

$$x_i(\tau) \approx \sum_k^{N_{ts}} y_{ik}(\tau) \quad (5)$$

where  $N_{ts}$  is the number of time slices required. Note that we write the relationship as approximate since the resampling implementation may have some inherent loss in quality. We note that by construction these filters are orthogonal over the index  $k$  since they are disjoint in time. In the next section we examine how to reduce the number of filters  $y_{ik}(\tau)$  via singular value decomposition to construct a set of filters that is also orthogonal within a given time slice.

**2.2.2. Reducing the number of filters with the singular value decomposition** As described previously, the template banks are, by design, highly correlated. It is possible to greatly reduce the number of filters required to achieve a particular minimum match by designing an appropriate set of orthonormal *basis templates*. A purely numerical technique based on the application of the singular value decomposition (SVD) to inspiral waveforms is demonstrated in [23]. Using the results of [23] we establish that the filters of the previous section can be approximated to

Symbol	Definition
$N$	The number of sample points in the data
$N_{x_i}$	The number of sample points in template $x_i$
$N_t$	The number of templates in the set $\{x_i\}$
$N_{ts}$	The number of time slices
$N_{u_j,k}$	The number of orthogonal filters in time slice $k$
$N_{ts,k}$	The number of samples in time slice $k$
$f_{\max}$	The maximum frequency of a filter
$f_k$	The sample frequency of the $k^{\text{th}}$ filter
$N_r$	The number of sample points in the resample filter

Table 2: Notation used to describe filtering. This table provides a quick reference for symbols used.

high accuracy by the expansion in the singular value basis

$$y_{ik}(\tau) \approx \sum_j^{N_{u_j,k}} \sigma_{jk} v_{ijk} u_j(\tau) \quad (6)$$

where  $\sigma_{jk}$  is the  $j^{\text{th}}$  singular value for the  $k^{\text{th}}$  time slice,  $v_{ijk}$  is an orthogonal matrix for the  $k^{\text{th}}$  time slice and  $u_{jk}$  is a new orthogonal basis filter set for the  $k^{\text{th}}$  time slice. The authors of [23] showed that to high reconstruction accuracy far fewer filters are needed than were in the original template bank. We find that when combined with the time-slice decomposition, the number of SVD filters,  $N_{u_j,k}$  is much smaller than the original number of filters  $N_t$ . We combine (6) with (5) to arrive at (3). In the next section we compute the expected computational cost scaling of this decomposition and compare it with the brute-force implementation in (1) and higher latency FFT methods.

### 2.3. Comparison of computational costs

We now examine the computational cost scaling of the approximate implementation of (1) as (3). An actual implementation of this decomposition in a working analysis pipeline is discussed in the next section along with measured computational requirements. For convenience, table 2 is a recap of the meaning of various symbols used in this calculation.

In table 3 we present the computational cost scaling in floating point operations per sample for common tasks in the pipeline.

The filter bank can be implemented using finite impulse response (FIR) filters, which are just sliding window dot products. If there are  $N_t$  templates of length  $N_{x_i}$  and the data stream contains  $N$  samples, then applying the filter bank requires  $2N_t N_{x_i} N$  operations.

More commonly, the matched filters are implemented using the FFT convolution. This entails applying FFTs to blocks of  $D$  samples, with  $N_{x_i} \leq D$ , each block overlapping the previous one by  $D - N_{x_i}$  samples. There are  $N/(D - N_{x_i})$  such blocks required to filter  $N$  samples of data. Modern implementations of the Cooley-Tukey FFT, such as the ubiquitous `fftw`, require about  $4N \lg N$  operations to evaluate a DFT

Process	ops/sample
FIR matched filter, $N_t$ templates of length $N_{x_i}$	$2N_tN_{x_i}$
FFT matched filter, $N_t$ templates of length $N_{x_i}$ blocks of length $D$	$\frac{4(N_t+1) \lg D + 2N_t}{1 - N_{x_i}/D}$
FIR resampling filter, length $N_r$ for each of $N_t$ templates and sample rates $f_1 < f_2$	$2N_tN_r f_1/f_2$
multiply $M \times L$ real matrix by $L \times 1$ real vector	$2ML$

Table 3: Number of floating point operations per sample (multiplications and divisions) required for a selection of signal processing operations used in LLOID.

of size  $N$  [32]. A  $D$  sample cross-correlation consists of a forward FFT, a  $D$  sample dot product, and an inverse FFT totaling  $8D \lg D + 2D$  operations per block. Per sample, this is  $(8 \lg D + 2)/(1 - N_{x_i}/D)$  operations. As this expression indicates the number of operations increases as the block size  $D$  approaches the filter length  $N_{x_i}$ .

The FIR filter implementation has the advantage that it has no intrinsic latency, whereas the FFT convolution has latency of  $D - N_{x_i}$ . However, the FIR filter implementation has the disadvantage of much greater overhead per sample than the FFT convolution. For a 1ks template sampled at 4096 Hz, the FIR implementation requires about  $N_{x_i}/8 \lg 2N_{x_i} = 2.2 \times 10^4$  times more operations per sample than the FFT implementation. We will now consider the computational cost of the FIR filter implementation described in the previous sections.

It is convenient to express the computational cost of the entire filtering procedure in floating point operations per second flop/s. The cost will be the sum of the cost of the FIR filtering for the orthogonal filter in each time slice plus the cost of reconstructing the original waveforms with matrix operations and resampling. Using the formulas in table 3 we arrive at

$$\text{C.C.} \propto 2 \sum_k^{N_{ts}} (N_{ts,k} + N_t) N_{u_j,k} f_k r \sum_{k, f_k \neq f_{\max}}^{N_{ts}} N_t N_r f_k \quad (7)$$

where the first sum is the total cost for filtering and reconstructing the orthogonal filters  $u_{jk}$ . The second sum is the cost of resampling the reconstructed time-slice outputs to the original sample rate  $f_{\max}$ . It assumes a FIR filter with  $N_r$  sample points. Note that the cost for resampling only occurs for the downsampled time slices. The resampling cost largely depends on  $N_r$ . The computational cost of (7) is dominated by the highest frequency terms in the sum. Comparing just the highest frequency term of (7) with (1) shows  $\mathcal{O}[(N_{ts,\max} + N_t) N_{u_j,\max} f_{\max}]$  flop/s versus  $\mathcal{O}[N_t N_{x_i} f_{\max}]$  flop/s. The full calculation for a particular patch of parameter space is shown in table ??.

FIXME we need to actually say what went into this

### 3. Results

In this section we test our implementation of the *nameless* method using the pipeline described in the previous section. We answer the following questions: I) What is the

*This is more commonly known as "overlap-save". We should find someone else's operation count and cite it. Drew: Why don't we change this to an overlap of m samples so we can see what happens as we increase the overlap to reduce latency.*

*From here down introduce an example, but don't go through the FFT methods in lloid focus just on the comparison of the TD method without lloid tricks, the FD method without lloid tricks, and the TD lloid method (no comp detection statistic though), remember that the goal is near realtime detection not computational cost*

measured loss of SNR due to the approximations used in the *nameless* algorithm in a realistic analysis pipeline? II) What is the measured latency of the implementation described in section ??? III) What is the measured computational cost of the implementation described in section ???

### 3.1. Measured SNR loss

We expect two contributions to the SNR loss to arise in our implementation of the *nameless* algorithm. The first is the SNR loss due to the truncation of the SVD basis, which is fundamental, and estimates for it exist [23]. The second comes from non ideal implementations of resampling that cause signal loss. We have measured the effect of the resampling in the pipeline alone on a single waveform to gauge the magnitude of the loss. It is shown in figure ?? as a function of the quality of the `audioresample` element (which is proportional to the filter length used). In both cases we have to compare the SNR loss to the expected SNR loss that arises from the discreteness of the template bank which is typically  $\sim 3\%$ . We will consider a comparable SNR loss to be tolerable, but ideally would like to have a factor of 10 lower loss from the *nameless* implementation (i.e. no more than  $\sim 0.3\%$ ).

It is also within reason that some SNR loss could arise from other suboptimal implementations of the *nameless* algorithm in our test pipeline. To gauge accurately how well the pipeline is performing we tested the response to a delta function. This should produce time reversed versions of the original template waveforms. By taking the innerproduct of the impulse response for each channel with the time reversed template, we can gauge very accurately the loss in expected SNR due to the approximations we have made and any inadequacies in our implementation.

*3.1.1. Checking the effect of the SVD tolerance* In this section we check the effect of the SVD tolerance parameter defined in [23]. By changing the tolerance of the reconstruction of the physical waveforms one effects directly the mismatch that results from the truncation of the orthogonal filter matrix. The conditions presented here are more complicated than in the original work [23] due to the inclusion of the time sliced templates and resampling. **However, we find that the results are quite as expected.** Figure 2 demonstrates that it is possible to achieve typical SNR losses of  $\ll 1\%$ . However, we do notice that the mismatch saturates with respect to the tolerance. This could be the effect of the resampling, or another SNR loss that we did not model or expect. However the saturation is still an order of magnitude below our target mismatch of  $\sim 0.3\%$ . We find that an SVD tolerance of  $1 - 1 \times 10^{-4}$  is adequate.

Figure 2: Box-and-whisker plot of mismatch between nominal template bank and *nameless* measured impulse responses. The SVD tolerance is varied from  $(1 - 10^{-1})$  to  $(1 - 10^{-6})$ . The diminishing improvement is caused by some other limitation in the pipeline.

*3.1.2. Checking the effect of the interpolation filter length* Next, keeping the SVD tolerance fixed at  $1 - 1 \times 10^{-6}$ , we checked the impact of changing the filter length used to interpolate the decimated data back up to the full sample rate. The results are in figure 3. We find that a filter length of 16 is sufficient to produce mismatches at our target of  $\sim 0.3\%$ .

### 3.2. Measured latency

In order to check the latency of our implementation of the *nameless* algorithm we used the pipeline described in ?? with a live source connected to the input. We then measured the timestamp of the live source and the output of the final SNR time series. Since *GStreamer* is not a sample-in-sample-out realtime infrastructure, it does work by passing small buffers of data and filtered data through the pipeline. We set the buffer size on the input to be 1/4 s. In an ideal case the latency should be nearly 1/4 s. However, it is necessary to queue things in the pipeline to assure that there are no issues with threading. Sometimes buffers get delayed. We measured the average filtering latency to be [1 s].

### 3.3. Measured computational cost

Using the pipeline described previously, we also measured the computational cost. We used an 8 socket, quad core AMD<sup>TM</sup> machine operating at 2.7 GHz per core. We found that filtering [657] templates in real time required about [6] of the available cores. We thus conclude that we require about 1 core for every [100] templates. We

Figure 3: Box-and-whisker plot of mismatch between nominal template bank and *nameless* measured impulse responses. The length  $N^\dagger$  of the interpolation filter is varied from 8 to 192. The SVD tolerance is kept fixed at  $(1 - 10^{-6})$ . The lines in the center of the boxes denote the medians. The upper and lower boundaries of the boxes show the upper and lower quartiles. The whiskers denote the minimum and maximum mismatch over all templates.

note that this is well within the computational limits of a modern, computing cluster assuming that the scaling holds for the entire mass range of interest, we would need about [300] cores per detector. This requirement should be even less of a burden in the advanced detector era, when presumably clusters built in that era will have a factor of 4 or 8 more cores than the ones today.

#### 4. Conclusions

We have demonstrated a computationally feasible procedure for the rapid detection of gravitational waves emitted during the coalescence of neutron stars and stellar-mass black holes. These sources are expected to produce prompt electromagnetic signals and may be the progenitors of some short hard gamma-ray bursts. Rapid alerts to the broader astronomical community may improve the chances of detecting an electromagnetic counterpart in bands from X-ray down to radio. We anticipate requiring no more than 1000 modern computer cores to analyze a four-detector network of gravitational-wave data for such systems assuming spin effects can be ignored in parameterizing the expected signals [?]. This is within the current computing capabilities of the LSC Data Grid [33].

The algorithm we described has no intrinsic latency. However, there are fundamental and practical latencies associated with the analysis and detection procedure. For example, the LIGO detectors, data acquisition is synchronized to a 1/16 Hz cadence introducing an up-front latency of 125 ms. Data aggregation from

the observatories will travel over various networks, each capable of high bandwidth but perhaps only modest latency. This could amount to a similar latency of  $\sim 100$  ms. Lastly, unless a realtime infrastructure is adopted post data acquisition, it is likely that there will be an inherent latency introduced by such infrastructure. We have shown a prototype implementation using `gstlal` that is capable of  $\sim 1$  s latency. In our opinion, significant work would have to be done in order to improve upon this number. However, it should be considered for third generation detector design. For example, a tighter integration of analysis and data acquisition would be beneficial.

We have omitted discussion of source localization. Localization is known to be poor for signals of low SNR [34]. However, one should not immediately dismiss the practical usefulness of a poorly localized source. Even with poor localization, it should be possible to begin downselecting what observatories could view a potential signal and for such observatories to begin any necessary prerequisite activities. In future works we will explore more rigorously the pointing prospects with realistic simulations using the infrastructure and techniques described in this work.

## Acknowledgments

LIGO was constructed by the California Institute of Technology and Massachusetts Institute of Technology with funding from the National Science Foundation and operates under cooperative agreement PHY-0107417. CH would like to thank Ilya Mandel for many discussions about rate estimates and the prospects of early detection. CH would also like to thank Patrick Brady for countless fruitful conversations about low latency analysis methods. NF would like to thank Alessandra Corsi for illuminating discussions on astronomical motivations.

This paper has LIGO Document Number LIGO-P0900004-v3.
